

# Karst Potential and Development Indices: Tools for Mapping Karst Hazard Areas Using GIS

James C. Currens

Matthew M. Crawford

Randall L. Paylor

Kentucky Geological Survey

University of Kentucky

# Introduction

Over half of Kentucky has karst - primarily defined by the presence of soluble (calcareous) bedrock at the surface.

The degree of karst development in the state is a serious planning and hazard issue that needs to be addressed on a statewide basis.

Environmental  
Issues

Sinkhole Collapse

Flooding

## Why a Kentucky Karst Index?

- Classification schemes bring order to a collection of observations as an aid to understanding the mechanisms leading to those observations. They can be utilized as planning tools.
- There have been many karst classifications proposed over the years, but most existing classifications are subjective and non-quantitative.
- Recent objective classification methodologies use labor-intensive site specific data for evaluation, and most of these methods do not use the types of data that are available statewide in Kentucky.
- The completion of the Digitally Vectorized Geologic Quadrangles for Kentucky along with new efforts to inventory statewide karst features now make it possible to evaluate the state's karst potential and development on a broad scale.

## Some Previous Classification Methods

- **DRASTIC - EPA Groundwater Sensitivity.**

*Hydrogeologic settings form the system and incorporate major hydrogeologic factors that control ground-water movement: depth to water, net recharge, aquifer media, soil media, topography, impact of the Vadose zone media and hydraulic conductivity of the aquifer.*

*Hydrogeologic settings are combined with these factors to create units to rank pollution potential.*

*Does not address karst issues effectively.*

- **KARSTIC - Adaptation of EPA methods to include karst groundwater flow.**

*Uses data not readily available in Kentucky.*

## Some Previous Classification Methods

- EPIK - European method.

*Uses four attributes: epikarst, protective cover, infiltration conditions and karst network development, rating and weighting them. Vulnerability depends on residence time of the water in very thick soil and sediment cover typical of alpine karst. Also takes infiltration through ponors into account.*

*Not effective for flat-lying Interior Plateaus province.*

- KISBC - Canadian method developed in British Columbia.

*The process considers three major criteria: 1) epikarst sensitivity; 2) surface karst sensitivity; and 3) subsurface karst potential. The procedure also allows for the integration of three modifying factors: 1) fine-textured, erodible soils; 2) karst roughness; and 3) unique or unusual flora/fauna and/or habitats.*

*Extremely field intensive and site-specific.*

## Defining Karst Potential and Karst Development

Karst Potential: A rank, based on stratigraphic and lithologic data, of areas that are subject to the development of caves, sinkholes, and springs.

Karst Development: A measure of “real world” karst based on the actual presence of caves, sinkholes, springs and similar features.

## Dual system approach

Although they are typically readily available, lithologic and stratigraphic data have not been widely used by themselves to indicate karst development.

This fact suggests that GIS stratigraphy layers must be calibrated with karst feature data before using the files to make karst maps.

We propose that such a dual potential-development approach can overcome pitfalls with either method alone, and produce a more accurate final product.

# Kentucky Karst Potential Map based on 500,000-scale geology

This map was compiled from a digital version of the 1:500,000-scale geologic map of Kentucky (Nolan, M.C., comp., 1980, Geologic map of Kentucky: U.S. Geological Survey). The areas of potential karst development were delineated using stratigraphic units mapped on the geologic map. The classification of the potential for karst development was based on the field experience of the authors and other data. A number of isolated carbonate units that would normally otherwise have been differentiated on the geologic map were newly digitized for this map.

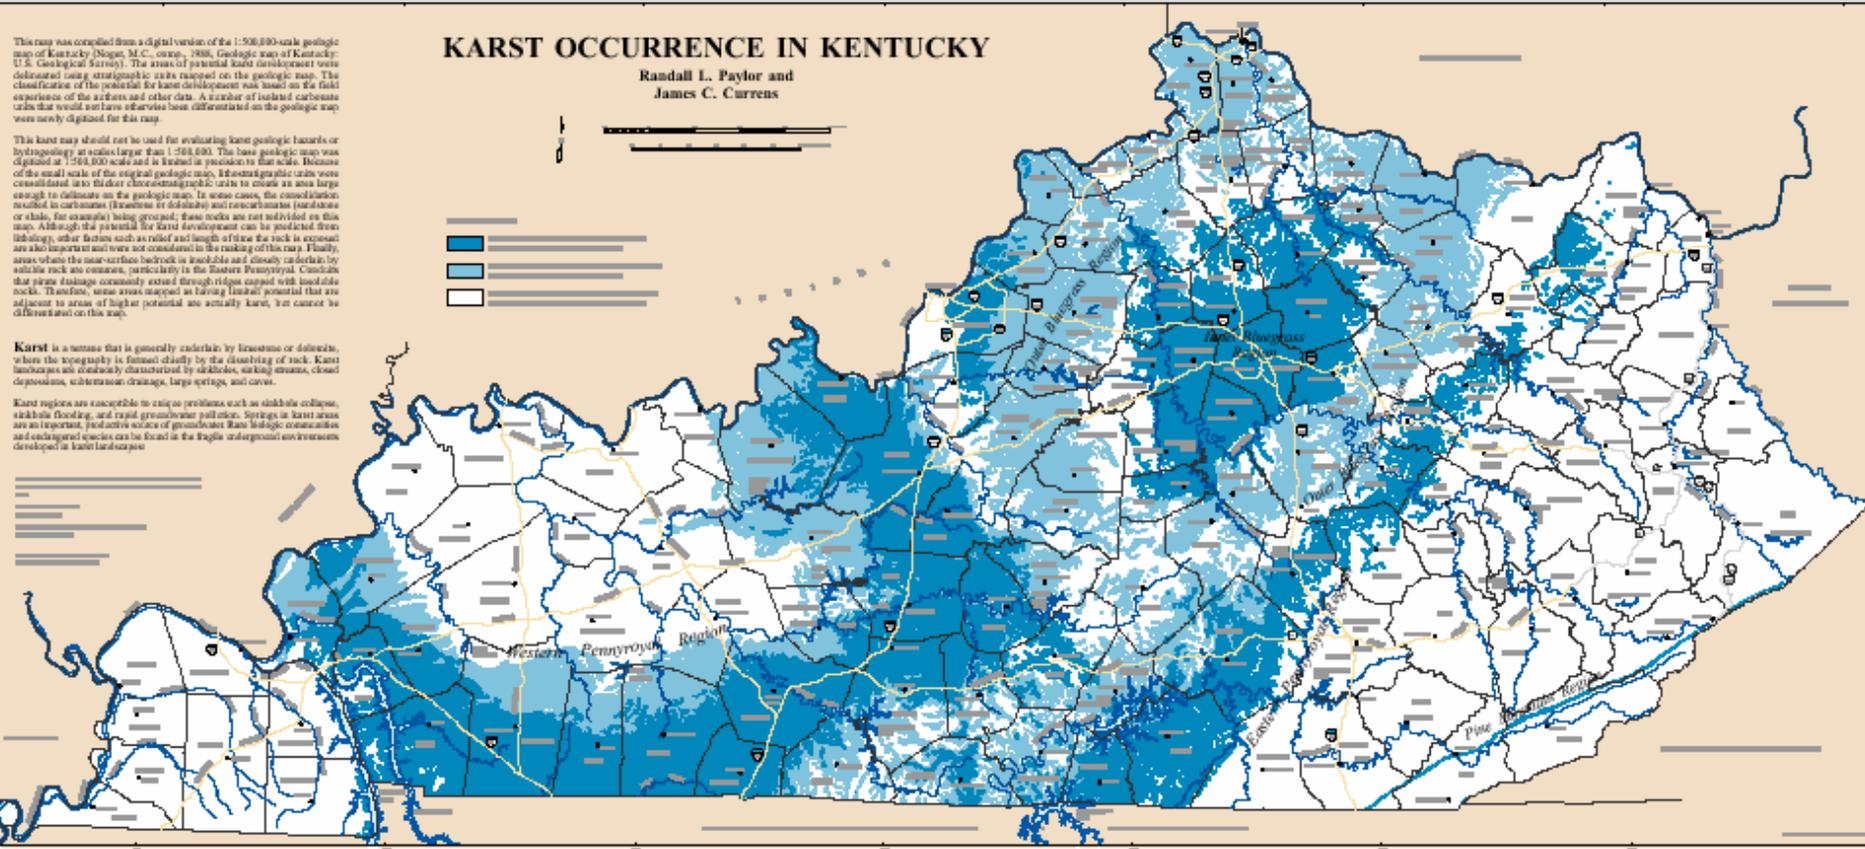

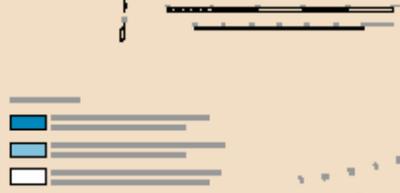

This karst map should not be used for evaluating karst geologic hazards or hydrogeology at scales larger than 1:500,000. The base geologic map was digitized at 1:500,000 scale and is limited in precision to that scale. Because of the small scale of the original geologic map, lithostratigraphic units were consolidated into thicker chronostratigraphic units to create an area large enough to delineate on the geologic map. In some cases, the consolidation resulted in carbonates (limestone or dolomite) and noncarbonates (sandstone or shale, for example) being grouped; these rocks are not subdivided on this map. Although the potential for karst development can be predicted from lithology, other factors such as relief and length of time the rock is exposed are also important and were not considered in the ranking of this map. Finally, areas where the near-surface bedrock is insoluble and closely underlain by soluble rock are common, particularly in the Eastern Pennsylvanian. Conditions that permit drainage commonly extend through ridges capped with insoluble rock. Therefore, some areas mapped as having limited potential that are adjacent to areas of higher potential are actually karst, but cannot be differentiated on this map.

**Karst** is a term that is generally understood to describe limestone or dolomite, where the topography is formed chiefly by the dissolving of rock. Karst landscapes are commonly characterized by sinkholes, sinking streams, closed depressions, subterranean drainage, large springs, and caves.

Karst regions are susceptible to unique problems such as sinkhole collapse, sinkhole flooding, and rapid groundwater pollution. Springs in karst areas are an important, productive source of groundwater. Rare biologic communities and endangered species can be found in the highly underground environments developed in karst landscapes.

## KARST OCCURRENCE IN KENTUCKY

Randall L. Paylor and  
James C. Currens

This map was compiled from a digital version of the 1:500,000-scale geologic map of Kentucky (Nages, M.C., comp., 1988, Geologic map of Kentucky: U.S. Geological Survey). The areas of potential karst development were delineated using stratigraphic units mapped on the geologic map. The classification of the potential for karst development was based on the field experience of the authors and other data. A number of isolated carbonate units that would not have otherwise been differentiated on the geologic map were newly digitized for this map.

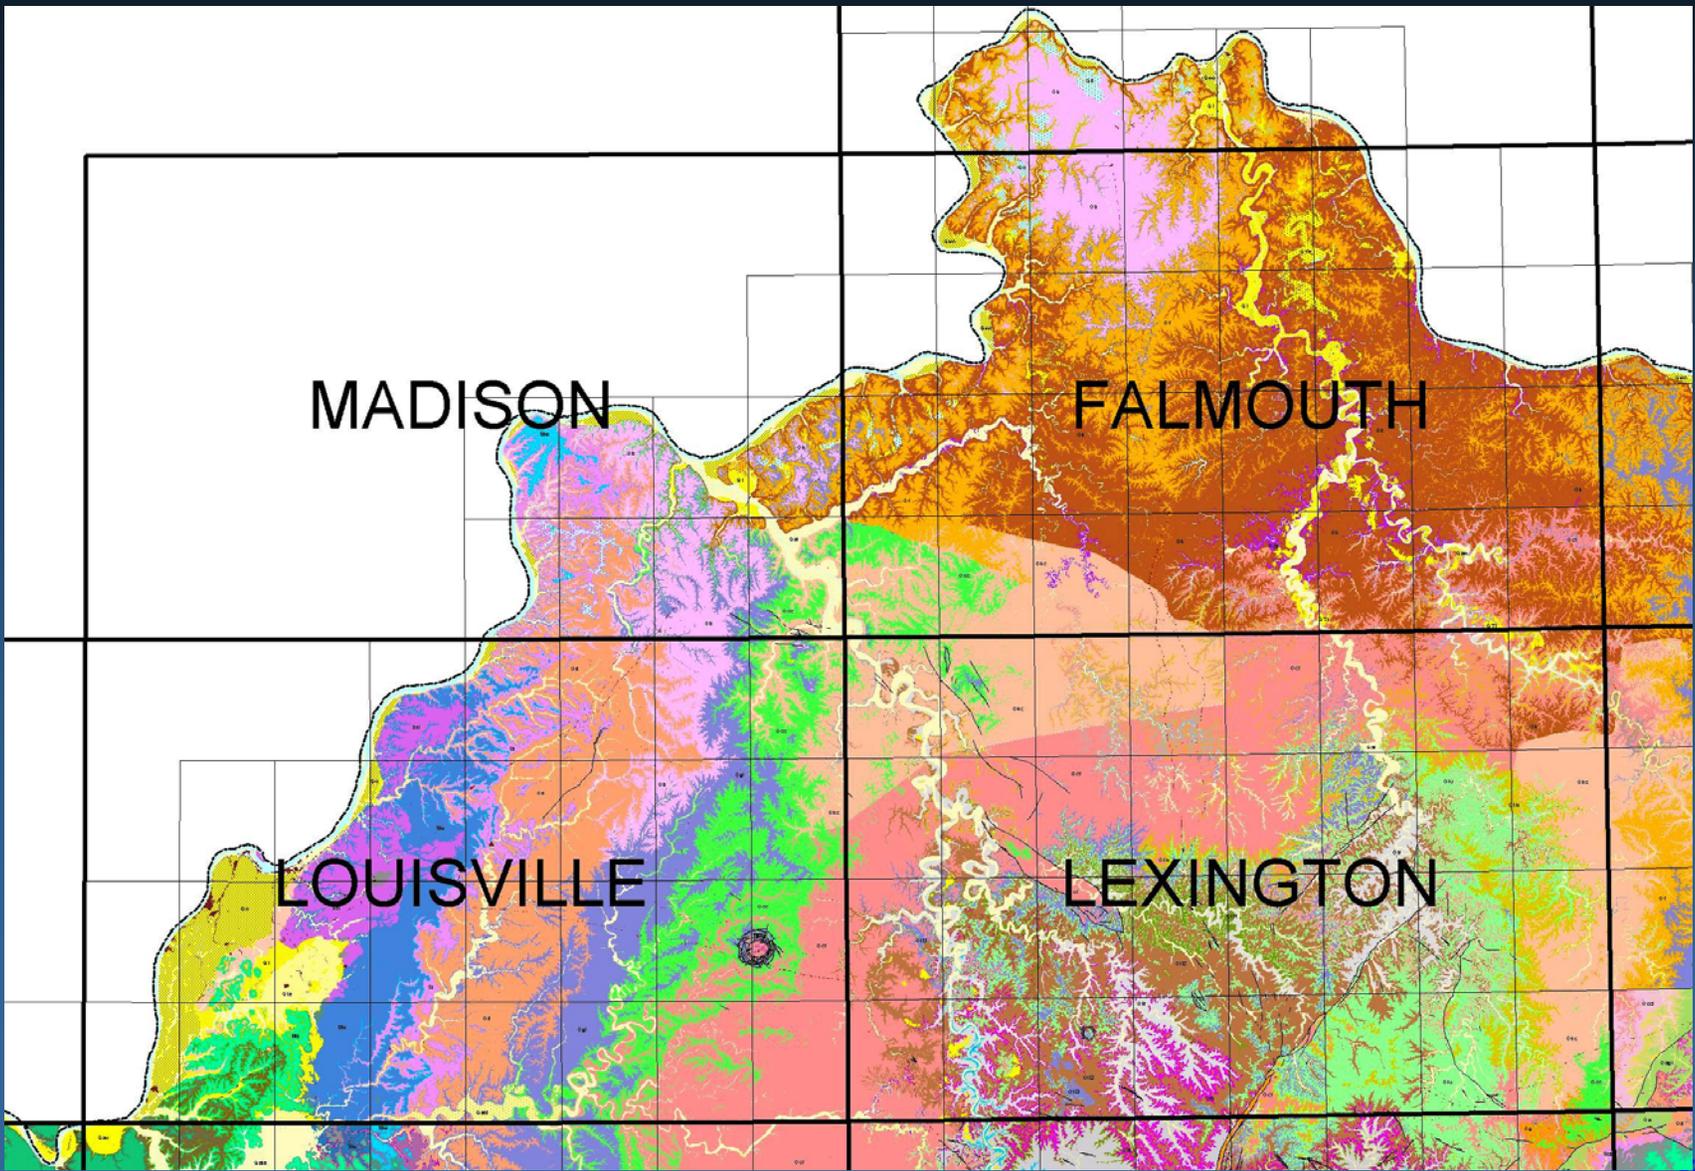

This karst map should not be used for evaluating karst geologic hazards or hydrogeology at scales larger than 1:500,000. The base geologic map was digitized at 1:500,000 scale and is limited in precision to that scale. Because of the small scale of the original geologic map, lithostratigraphic units were consolidated into thicker chronostratigraphic units to create an area large enough to delineate on the geologic map. In some cases, the consolidation resulted in carbonates (limestones or dolomites) and noncarbonates (sandstone or shale, for example) being grouped; these units are not subdivided on this map. Although the potential for karst development can be predicted from lithology, other factors such as relief and length of time the rock is exposed are also important and were not considered in the making of the map. Finally, areas where the near-surface bedrock is erodible and closely underlain by soluble rock are common, particularly in the Eastern Pennsylvanian. Conclude that some drainage commonly erode through ridges capped with insoluble rocks. Therefore, some areas mapped as having limited potential that are adjacent to areas of higher potential are actually karst, but cannot be differentiated on the map.

**Karst** is a term that is generally understood by limestones or dolomites, where the topography is formed chiefly by the dissolving of rock. Karst landscapes are commonly characterized by sinkholes, sinking streams, closed depressions, subterranean drainage, large springs, and caves.

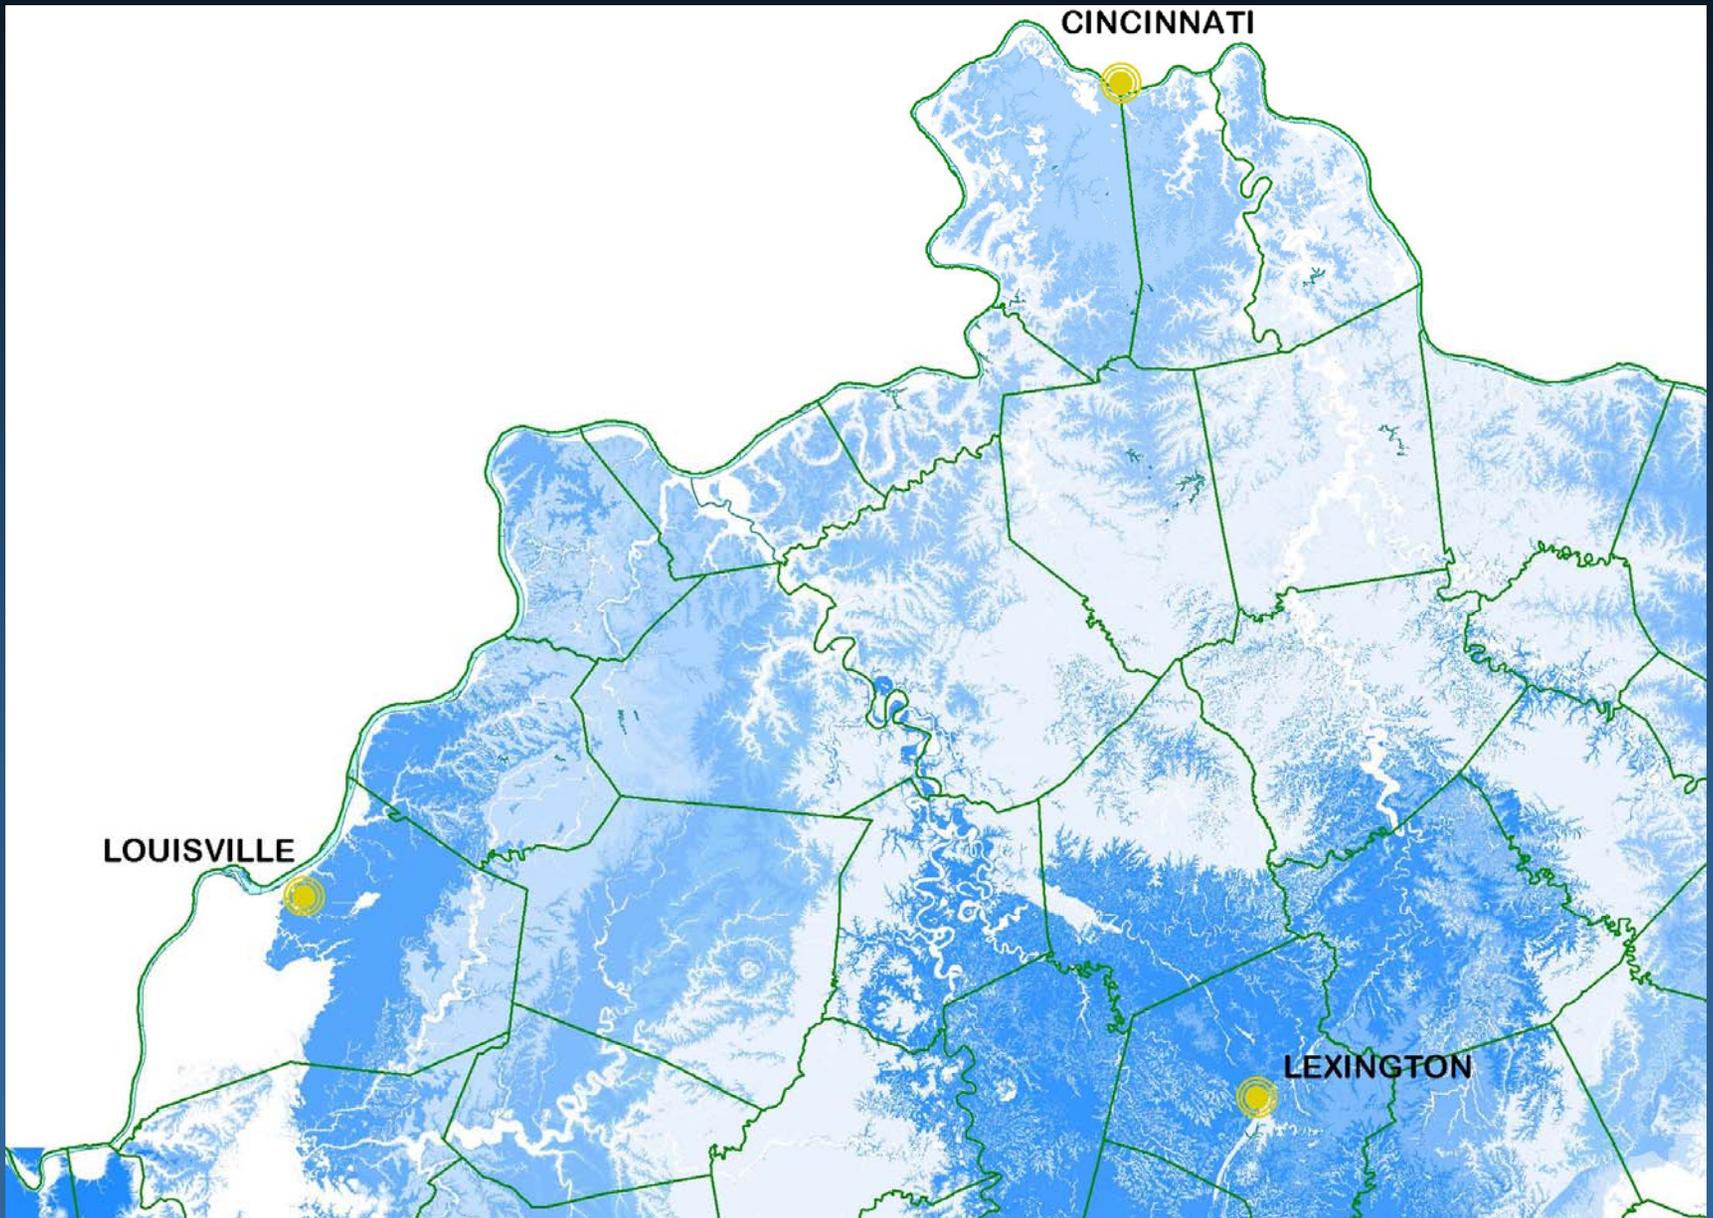

Karst regions are susceptible to such as problems such as sinkhole collapse, sinkhole flooding, and rapid groundwater pollution. Springs in karst areas are an important, productive source of groundwater. Rare biologic communities and endangered species can be found in the fragile underground environments developed in karst landscapes.

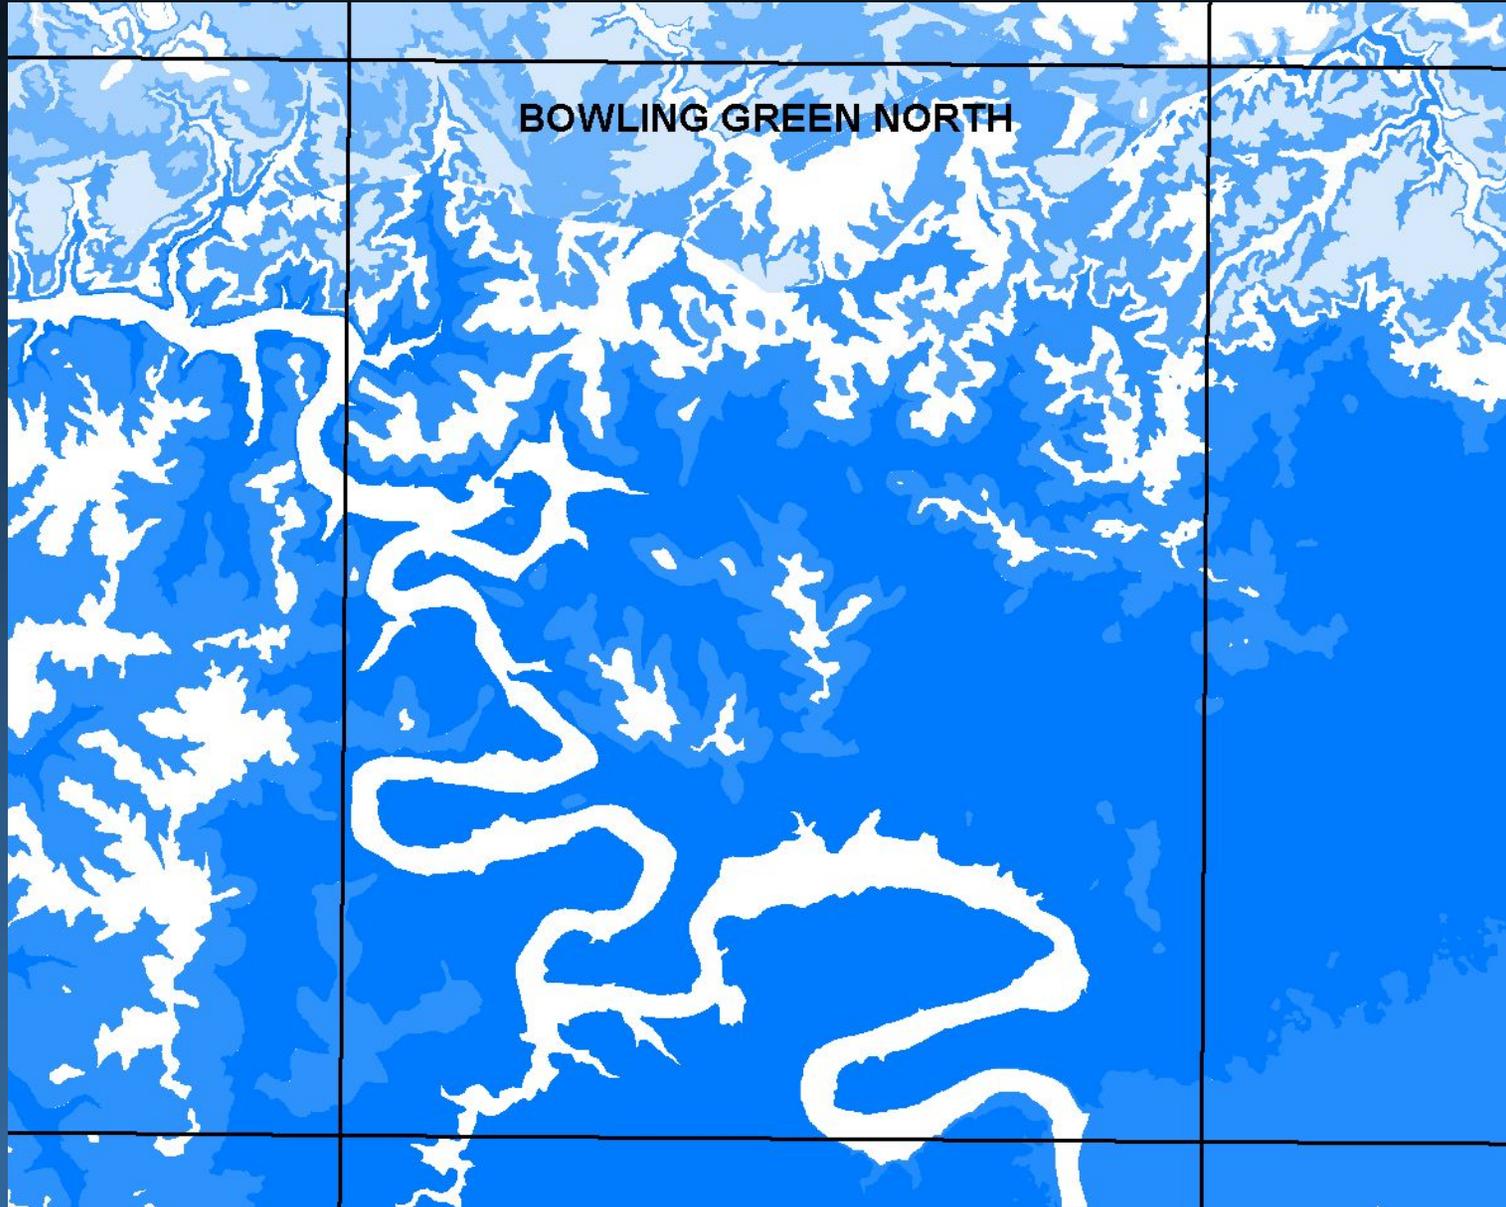

# Final Karst Index applied to DVGQs - Original Data

# Final Karst Index applied to DVGQs

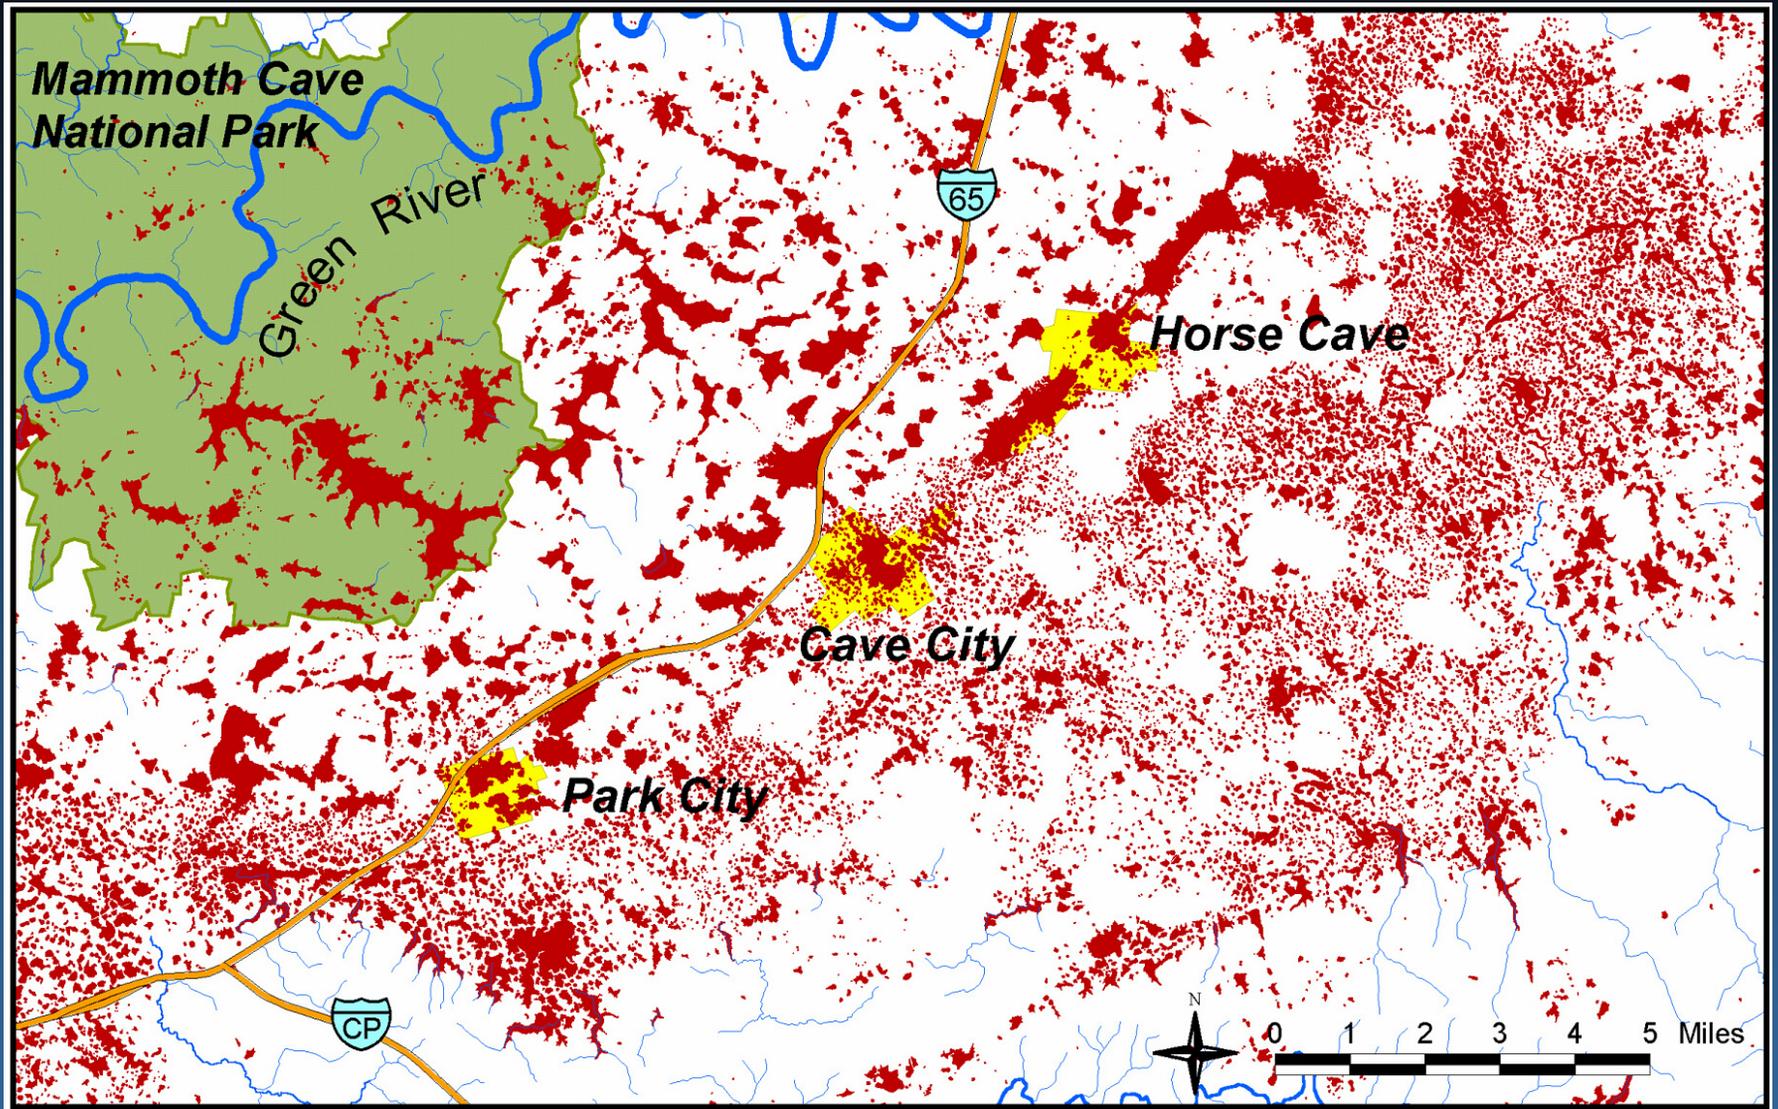

# Final Karst Index applied to DVGQs

## DISCUSSION

- The KDI/KPI project has developed a regional karst classification method that is more appropriate for Kentucky and the Interior Plateaus province than previously used methods.
- The KDI and KPI methods correlate well, suggesting that they are good criteria for classifying karst in Kentucky.
- The detailed karst maps produced from this study can aid in many areas, including planning, hazard evaluation and environmental investigations.
  - Groundwater issues are not directly addressed using the KDI/KPI classification, but it can be used to augment karst groundwater classification methods. Does not currently address non-karst catchments draining onto karst areas.
- The classification system proposed here does not remove the necessity for field investigations when evaluating site specific karst issues.

Map represents 3337 cave entrances with known location data.  
Another ~1100 caves included in the KSS files have little or no  
location data. 318 new cave locations have been added in 2006.

## Further Work

- The KDI as currently calculated is based on four 100K quad sheets. The KDI will be evaluated for all the remaining quads and recalculated for more accurate results.
- Investigate the use of relief (derived from DEMs) to further refine the KDI matrix.
  - Address the problem of “quad boundary faults” where necessary.
- Include the final Karst Index map as a base layer on the KGS Internet Map Server.
